Abstract

Few studies have been carried out to investigate the Patient's involvement in the decision-making process in the healthcare system. Here, we perform advanced analysis as a follow up to our previously developed mathematical healthcare business model involving three populations. The advanced model contributes to healthcare economic modelling by analyzing the stochastic cooperation behavior of agents within three proposed populations: *Public Healthcare Providers*, *Private Healthcare Providers* and *Patients*. By employing agent-based simulations and methods from Evolutionary Game Theory (EGT), we study cooperation outcomes within each population. We study the effect of increasing mutation or behavioural exploration rate and that of unequal population sizes of healthcare providers and patients. We show that the former introduces more randomness in agents' behaviors enabling cooperation to emerge in more difficult conditions. We also find that, when the Providers' capacity is limited (i.e., small population size), the Patients exhibit lower levels of cooperation, implying a more difficult cooperation dilemma that needs solving.

Introduction

The healthcare system in the UK is regulated by the Department of Health where explicit rules, activities and mechanisms are imposed and enforced by the state to manage social behavior (Saltman, 2002). From the perspective of UK health policy, the tendency is to understand an incentive as an economic inducement or benefit, whether tangible or intangible, resulting from a behavior that impacts the performance of the healthcare system, whether positively or negatively. This narrow definition tends to exclude non-monetary incentives or benefits (Grant, 2003; Saltman, 2002). This dilemma can be solved pragmatically by the introduction of Evolutionary Game Theory (EGT). EGT provides various examples that can be followed such as the Public Goods Game (PGG) where individuals can get a share of the benefits of cooperation equivalent to their collective contribution to upholding the process (keep it going).

In this research, we investigate the evolution of cooperation in a complex system, namely the healthcare system in England, which is made up of populations

consisting of different healthcare providers interacting with patients. Our investigation examines individual agents' behaviors as viewed by an external policymaker, in this case, the Health Department. Generally, policies are initiated and managed by the Health Department, which allocates a specific budget to interfere.

To this end, our analysis here is carried out based on a baseline model we developed in (Alalawi et al., 2019). This previous work focuses on numerical analysis of the proposed healthcare model, studying evolutionary dynamics of three well-mixed finite populations. The analytical approach we adopted therein relied on the assumptions of rare behavioral mutation by the agents, and that all populations having an equal size. Our finding shows that agents from all three populations tend to not cooperate (i.e. defect) (Alalawi et al., 2019). While these simplified assumptions allowed us, as a very first step, to provide clear mathematical analysis, they prevented us from analysing some important factors. Namely, mutation or behavioural exploration, where agents can freely experiment with new behaviors, has been shown to play an important role in enabling cooperation in the context of social dilemmas (Duong and Han, 2019; Antal et al., 2009; Traulsen et al., 2009; Han et al., 2012). As the world is facing a rapid increase in populations, most healthcare capacity is struggling to cope with attendant mounting demand and to accommodate growing populations' needs. Moreover, some scholars have warned that, in reality, healthcare providers might not be able to meet the treatment demand from all patients (Ewbank et al., 2020). It is, therefore, viable to investigate this intensifying trend and study the ratio of population to hospital bed availability. Currently in England, UK, the number stands at 474 patients per hospital bed¹. (Office for National Statistic, 2020)

Therefore, in this paper, we develop agent-based

¹England population number was obtained from Office for National Statistic ONS (correct as of mid-2019), available at: <https://bit.ly/2MCb3yc>. The number of hospital beds in England (correct as of 2018/9) was calculated based on data provided by the King's fund report "NHS hospital bed numbers: past, present, future": <https://bit.ly/2UfgeZ0>; (accessed 6 June 2020).

simulations of this baseline model to investigate how relaxing the above-mentioned assumptions affects the cooperation outcomes in providers' and patients' populations. Namely, we seek to develop a more insightful understanding of the dynamical behavior of agents in each population, the effects of applying a large mutation/exploration rate on the abundance of cooperation, and the influence of reduced sizes of the healthcare providers' population on the agent's behavior within the dynamic system and their population.

The rest of this paper is structured as follows. Related Work section reviews the most relevant literature. Model and Methods section presents our healthcare model and methods applied. Results and Discussion section discusses agent-based simulation results. The conclusion summarises our findings and explores their implications for future work.

Related Work

Researchers eager to understand the behavior of different agent representations within the healthcare system use AI (Ziuziański et al., 2014), game theory (Agee and Gates, 2013; Wu et al., 2016), multi-agents system (De and Gelfand, 2017) and big data (Murdoch and Detsky, 2013) which are used to predict and understand behaviors within systems. However, little effort has been made to study the dynamics of cooperation and other decision making in the healthcare domain, which usually involves different actors in the decision making processes. Our previous work (Alalawi et al., 2019) and this work aim to bridge this important gap by resorting to population-based methods from EGT to develop an understanding of the dynamics of cooperative behaviour in this domain.

The rapid development in research on the learning of social behavior has significantly increased our understanding of the dynamic interaction among individuals from different populations (Sigmund, 2010). Cooperation is one of the fundamental aspects to measure the strength and dynamism of a population (Smith, 1974; Kurokawa and Ihara, 2009; Encarnação et al., 2016). It can be studied by applying EGT to different mechanisms, such as reciprocal behaviors, kin selection and costly incentives (Sigmund, 2010; Hofbauer and Sigmund, 1998). EGT has been successfully used across major scientific fields such as biology, ecology, economics, psychology and mathematical computation (Sigmund, 2010; Hofbauer and Sigmund, 1998).

Model and Methods

Healthcare Model

In this section, we summarise the model presented in (Alalawi et al., 2019), where we consider three populations: Public providers $P1$, Private providers $P2$ and Patients $P3$. While $P1$ represents the NHS

Parameters' description	Symbol
Reputation benefit for the Public and Private healthcare providers	b_R
Patient's benefit	b_P
Cost of investment spent by the Public/Private healthcare provider	c_I
Cost of treatment acquired by the healthcare provider	c_T
Cost of healthcare management	c_M
Extra Patient's benefit when both providers cooperate	ε

Strategies			Payoffs		
P1	P2	P3	Public	Private	Patient
C	C	C	$b_R - c_I - c_T$	$b_R - c_I - c_M$	$b_P + \varepsilon b_P$
C	C	D	$-c_I$	$-c_I$	0
C	D	C	$b_R - c_I - c_T$	0	b_P
C	D	D	$-c_I$	0	0
D	C	C	0	$b_R - c_I - c_M$	$b_P - c_T$
D	C	D	0	$-c_I$	0
D	D	C	0	0	$-c_T$
D	D	D	0	0	0

TABLE 1: The healthcare model (Public: $P1$, Private: $P2$, Patient: $P3$).

or the public healthcare providers, $P2$ represents independent healthcare providers $P2$ selling healthcare services, and $P3$ represents those who seek personal treatments. Agents from each population ($P1$, $P2$ and $P3$) can choose from two strategies: provide/accept sustainable treatment identified as cooperating, otherwise the game will be dominated by alternative treatments from other providers. On each game encounter or iteration, an agent's payoff is acquired based on the strategy played by each agent/individual from the three populations. In this game, an interaction happens among three agents, one from each of the three populations, see Table 1.

An agent in each of the three populations has two strategies, *cooperate* (C) and *defect* (D). Here the strategy coincides with the action of an agent, despite the fact that there is only one decision to make, which can be interpreted as follows.

Public healthcare providers:

- C : offers treatment paid for from taxpayers' money, which consists of paying a cost c_I , and in return gets a reputation benefit.
- D : does not want to pay for the treatment.

Private healthcare providers:

- C : offers treatment either paid by Public (when Public cooperates) or self-paid by Patient (so the main cost involved is management cost c_M), and obtains a reputation benefit b_R . In case of cooperation with the Patient, Private commits to investing c_I from its revenue.

- D : does not want to offer the treatment.

Patient:

- C : accepts being treated and pays for the treatment c_T when treated by the Private; Patient obtains health benefit b_P if at least one provider cooperates and extra health benefit when both providers cooperate ε .
- D : rejects the treatment and looks for alternative treatment mostly overseas, where above conditions are correct, and: $b_P > 0$, $\varepsilon > 0$ and $c_T > 0$.

Thus, given the strategies of players in each population, there are 8 possible strategic combinations or scenarios, represented by XYZ where X, Y, Z can be either C or D. We summarize a few of them below (full details can be found in (Alalawi et al., 2019))

- CCC : individuals from all three populations choose to cooperate. The Public pays for the treatment provided by a Private healthcare provider and the Patient accepts the provided treatment in pursuit of her/his own benefit or well-being. The Public, which bears the costs of investment and pays for the Patient's treatment ($c_I + c_T$), covered from its allocated budget, gains a reputation benefit b_R . Reputation benefits are derived from the Patient's satisfaction with the provided service. On the other hand, the Private healthcare provider will provide the required treatment to the Patient and receive the payment covering the costs from the Public. The cost of investment c_I of the Private healthcare provider is to invest in staffing and healthcare facilities, while c_M refers to administrative and operational costs. Also, the Private provider will obtain a reputation benefit with the Public b_R . Patient gets extra health benefit εb_P as both healthcare providers are cooperating (ε represents a synergistic factor).
- DDD : this scenario consists of all three agents choosing not to interact with one another, thus all the agents get a zero payoff.

Method: Evolutionary Dynamics for Three Populations

EGT method is adopted to study the evolutionary dynamics and interactions among individuals from three distinct finite populations: $P1$, $P2$ and $P3$. The populations are of fixed sizes N_1 , N_2 and N_3 , respectively. In each time step, from a randomly selected population, a randomly selected individual A with fitness f_A imitates another randomly selected individual B with f_B fitness using the pairwise comparison rule, a popular and standard approach to implementing social learning in EGT (Sigmund, 2010; Traulsen et al., 2007). Namely, the probability ρ that A adopts B 's strategy is given by the Fermi's function

$$\rho = [1 + e^{-\beta[f_B - f_A]}]^{-1}, \quad (1)$$

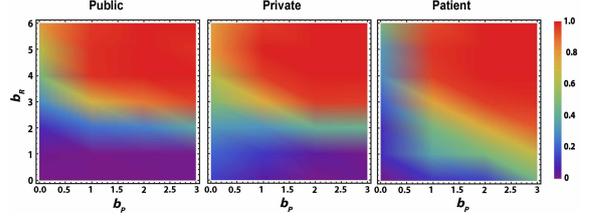

FIGURE 1: The cooperation level in each of the three populations as a function of the sectors' benefit b_R and patient's benefit b_P . Other parameters: c_I , c_T , $c_M = 1$; $N_1, N_2, N_3 = 100$; $\varepsilon = 0.2$; $\mu = 10^{-4}$; $\beta = 0.1$.

where $\beta > 0$ represents the 'intensity of selection' or 'imitation strength'; $\beta = 0$ represents neutral drift where imitation decision is random, while for $\beta \rightarrow \infty$ the imitation decision is increasingly deterministic.

When mutation or behavioral exploration (Gokhale and Traulsen, 2010; Duong and Han, 2019) is not rare (which is different from the analysis in (Alalawi et al., 2019)), we consider that, before A considers to imitate B , with a probability μ , it changes to a randomly selected strategy from its behavioural space (in this case, C or D). That is, with probability $(1 - \mu)$ A considers to imitate B as above.

Individuals in each population have the choice to C or to D in a paradigm shift fashion. As described above, there are eight possible paradigms or scenarios corresponding to the eight possible combinations of the strategies within the three populations: CCC , CCD , CDC , CDD , DCC , DCD , DDC , DDD . Denoting the numbers of cooperators in $P1$, $P2$ and $P3$ by x , y , and z , respectively, the payoff of each strategy can be written as follows:

$$\left. \begin{aligned} P_s^{Public}(x, y, z) &= P_{syz} \\ P_s^{Private}(x, y, z) &= P_{xsz} \\ P_s^{Patient}(x, y, z) &= P_{xys} \end{aligned} \right\} \text{Pairwise comparison} \quad (2)$$

where P_{xyz} is the payoff for the strategy selected by individuals from one of the stated populations, and (x, y, z) represents the selected strategies C or D . For instance, individuals from $P1$ have the options to play C or D . The selected strategy will replace the s at x vertex, while y and z vertices remain unchanged for selected strategies for the Public population in this instance.

$$\begin{aligned} Public &\rightarrow f(Cyz) > P_{Dyz} \\ Private &\rightarrow f(xCz) > P_{xDz} \\ Patient &\rightarrow f(xyC) > P_{xyD} \end{aligned} \quad (3)$$

Agent-based Simulations

As mutation is not rare, we perform agent-based simulations to study the evolutionary dynamics. Initially, agents in the three populations are given a random strategy (C or D). In each generation or time step, agents' fitness is calculated as in Table 1. Namely, the fitness of an individual adopting a strategy s within a population is derived from the average obtained from the tripartite one-shot game described in Table 1. A randomly selected individual in each game obtains

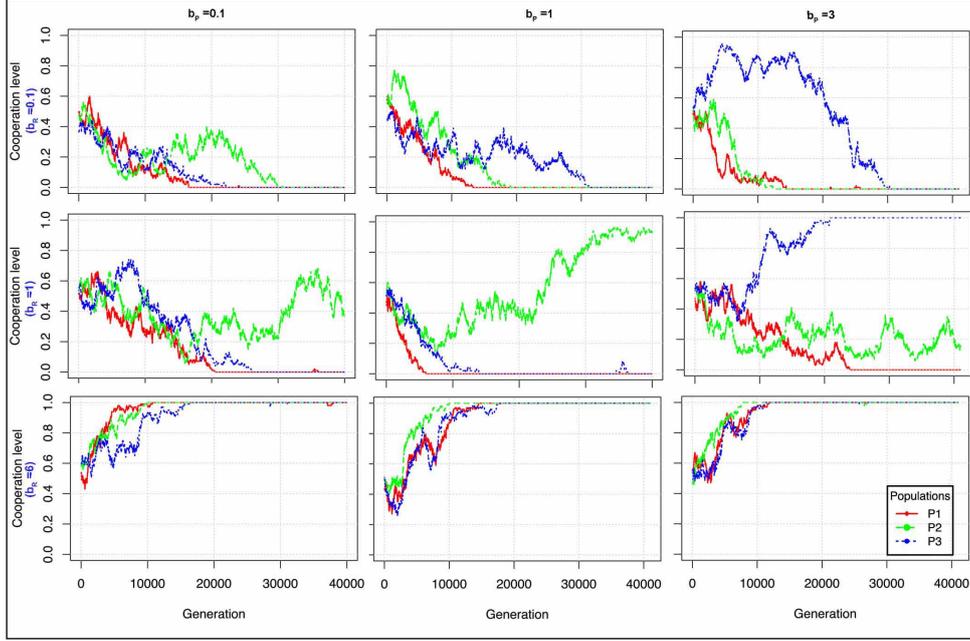

FIGURE 2: Typical simulation runs showing the cooperation levels over time in the three populations (red for Public, blue for Private and green for Patient). The plots represent the frequency of cooperation adopted by the populations for different values of b_R and b_P . Other parameters as in Figure 1.

an average payoff given by (Encarnaçao et al., 2016; Santos et al., 2016):

$$f_S^{Public}(x, y, z) = yzP_{SCC}^{Public} + (1 - y)zP_{SDC}^{Public} + y(1 - z)P_{SCD}^{Public} + (1 - y)(1 - z)P_{SDD}^{Public},$$

$$f_S^{Private}(x, y, z) = xzP_{CSC}^{Private} + (1 - x)zP_{DSC}^{Private} + x(1 - z)P_{CSD}^{Private} + (1 - x)(1 - z)P_{DSD}^{Private},$$

$$f_S^{Patient}(x, y, z) = xyP_{CCS}^{Patient} + (1 - x)yP_{DCS}^{Patient} + x(1 - y)P_{CDS}^{Patient} + (1 - x)(1 - y)P_{DDS}^{Patient},$$

where $f_S^P(x, y, z)$ represents agents' average payoff in a population P while adopting strategy s , assuming that the population is present in the vertices (x, y, z) . P_{ABC}^S denotes the payoff that an individual playing in a group with a strategy profile derives from state S where public plays A , private plays B and patient plays C . These payoffs are shown in Table 1.

Each simulation of the stochastic modelling runs for a number of generations (at least 40,000), where a stable state is reached in general (see examples in Fig. 2). To ensure accuracy, the accumulated results are then averaged over the last 100 time steps, and furthermore, for each parameter configuration, the results were averaged over 50 independent realisations. As mutation is adopted in the simulations, no absorbed monomorphic state is reached.

Results and Discussion

In this study we conduct agent-based simulations (see Methods), where agents from the three populations $P1$, $P2$ and $P3$ interact in a one-shot game and learn how they influence the level of cooperation to sustain cost-effective services and better patient satisfaction.

Figure 1 shows the cooperation levels adopted in the populations for varying the sectors' benefit b_R and patient's benefit b_P . In general, cooperation in all populations is most abundant when both benefits are sufficiently large. The two sectors have similar cooperation for the whole parameter space, except when both benefits are small, where the private sector has a slightly higher level of cooperation.

To better understand the detailed dynamics, in Figure 2 we show the evolution of cooperation over time in each population for different combinations of the benefits. Indeed, we can see that when b_R is large (see $b_R = 6$, bottom row), all the three populations quickly converge to full cooperation even for small

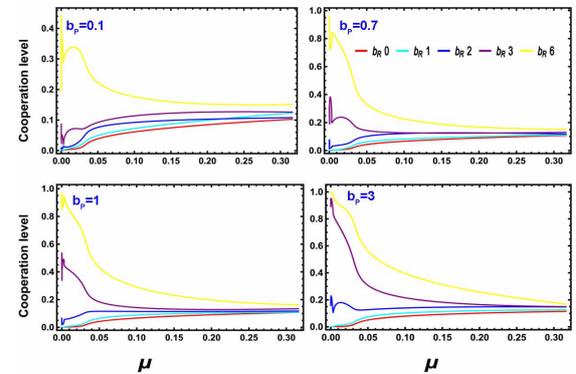

FIGURE 3: Frequencies of CCC for increasing mutation rate, μ . It represents the trends of different b_R values for the stated value of b_P on each plot. Other parameters as in Figure 1.

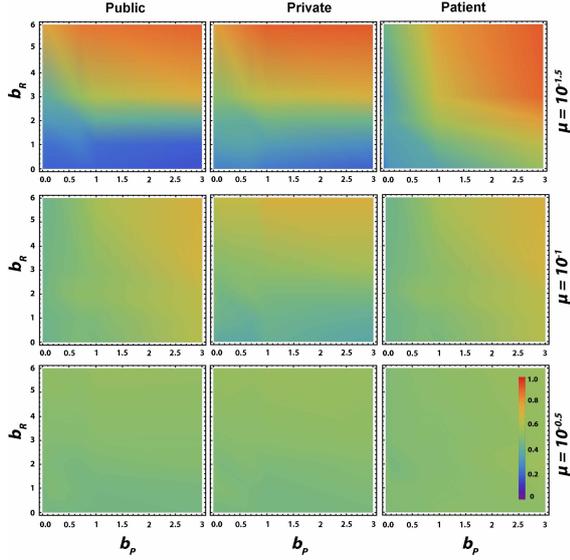

FIGURE 4: Cooperation levels in three populations for different values of μ . First column for $P1$, second column for $P2$, and third column for $P3$. μ values are as specified on the right side. Other parameters as in Figure 1.

b_P . For intermediate b_R (see $b_R = 1$, middle row), $P1$ converges to defection, while $P2$ still maintains some level of cooperation and $P3$ have high levels of cooperation when b_P is large (i.e. equals 3). When b_R is small, all populations converge to defection. That is, $P2$ population is more willing to cooperate with $P3$ for quite low b_P (where $b_P \leq 1$ and $b_R \leq 1$). On the other hand, $P3$ requires better reputation benefit b_R to cooperate with $P3$ and provides the desired services. As a consequence, $P3$ has to pay extra cost equivalent to c_T as represented in Table 1, i.e: DCC for the Patient's payoff ($b_P - c_T$) compared to the other scenarios, CCC or CDC , where the cost equals zero.

The effect of mutation

We now study how increasing the mutation rate μ affects the cooperation outcome in each population. Note that so far we consider rare mutation or low mutation rate $\mu = 10^{-4}$, recovering results from our previous work using small mutation dynamics (Alalawi et al., 2019). Fig. 4 shows results for higher mutation rates, namely, $\mu = 10^{-k}$, with $k = 1.5, 1$ and 0.5 . As expected, as larger mutation leads to greater levels of randomness in agents' behaviors, we observe more defection in scenarios where cooperation is abundant (high benefits), and vice versa, i.e. more cooperation in previous scenarios with abundant defections. Interestingly, for intermediate μ ($\mu = 10^{-1}$), $P1$'s cooperation mostly depends on $P3$'s benefit, while $P2$ is more dependent on the reputation benefit. This observation can also be seen in Fig. 3, where we plot the frequency of CCC . For sufficiently large μ , the frequency of CCC always converges to $1/8$ regardless of

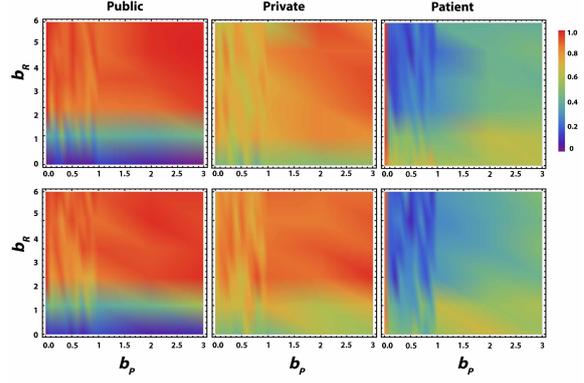

FIGURE 5: Cooperation levels in each population based on the ratio of hospital bed availability provided by healthcare providers compared to the size of the $P3$ population ($N_3=100$). Where the size of the $P1/P2$ is: first row $N_1 = N_2 = 10$ and second row $N_1 = N_2 = 5$. Other parameters as in Figure 1.

the values of the benefits, which is when all populations converge to 50% cooperation.

The effect of unequal population sizes

In reality, the availability of hospital beds is very limited for the increasing number of patients; i.e: winter long waiting time in A&E or in a pandemic (e.g. as is the case with the COVID-19). We study the effect of this factor by looking at different providers' population size ratios to that of the Patient's population. Fig. 5 shows simulation results for two different providers' sizes, 10 & 5. The results reveal that $P2$ cooperates more with lower providers' and patients' benefits. Whereas the $P1$ population still prefers to cooperate with higher reputation benefit b_R . Conversely, $P3$ shows a significantly different behavior in the decision making process by defecting upon low health benefit $0.1 < b_P < 1$ and willing to cooperate when $b_P < 0.1$ and $b_P \geq 1$ for larger providers' population sizes.

These observations show that, in a more realistic setting where both $P1$ and $P2$ usually have a lower capacity than what is required by $P3$, it is more difficult to ensure cooperation from the patients. That is, the cooperation issue is more severe, which therefore requires additional supporting mechanisms such as incentives to maintain cooperation. We are currently studying this important setting.

Concluding Remarks

We have studied cooperation outcomes and evolutionary dynamics of a three-population healthcare model using extensive agent-based simulations. We analyze cooperation outcomes for incremental rate of mutation, and compare them with those when it is rare, as reported in our previous work. This result can represent realistic scenarios derived from some elective treatments such as hip replacements (Moscelli et al.,

2016). To link our model to realistic scenarios it will make use of data published by the NHS and complemented with figures obtained from the Patient Reports Outcome Measures (NHS Digital, 2019) and the Care Quality Commission (CQC, 2019).

We found abundance of cooperation closely linked with high benefits. Interestingly, for sufficiently high mutation rates, more cooperation also emerged in scenarios that are previously dominated by defection in all populations.

We explored the influence of reducing the size of the healthcare provider population on cooperation between the three populations. We compared the results of two different healthcare provider population sizes (10 & 5) providing medical services to 100 patients. We found that the Patient is less likely to cooperate (small abundance) when the Provider populations are small, which means that providers have a limited capacity to accommodate the patients' needs. This finding reveals a critical cooperation problem that needs to be resolved. We plan to explore new mechanisms to improve cooperation in this important and realistic setting, such as via positive or negative incentives in the form and institutional rewards and punishments.
